

Lecture XV: Diastereomers of Alkenes

02-19-2020

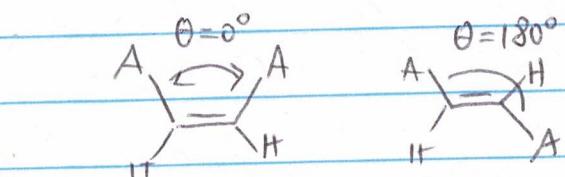

Alkenes are a broad class of generally planar compounds, which can show cis-trans isomerism:

σ -bond between sp^2 hybridized carbons
 $\sim 83 \text{ kcal/mol}$

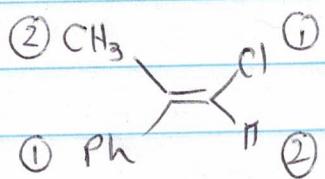

Cis/trans isomers are stable, configurational isomers. They are diastereomers of one another:

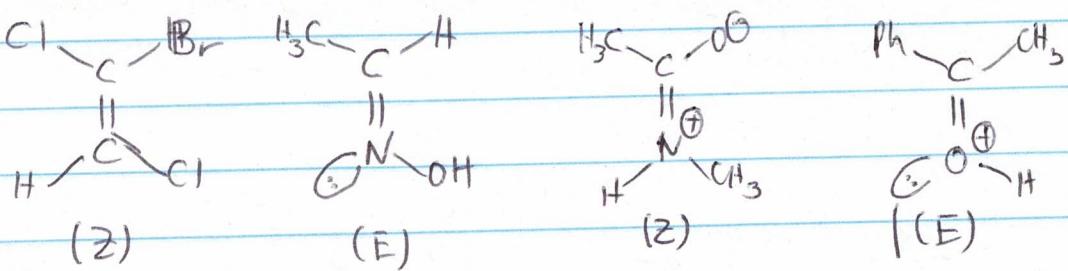

The alkene isomers differ in their torsional angles, and cis-trans designations apply to disubstituted alkenes when they are roughly coplanar. Also, the barrier to interconversion must be high.

E/Z nomenclature is more general and it applies to a greater range of substitution patterns.

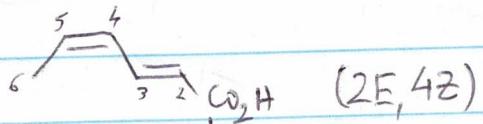

According to CIP rules. If ①s are on the same side \Rightarrow Z (zusammen, together)
 ①s on opposite sides \Rightarrow E (entgegen, opposite)

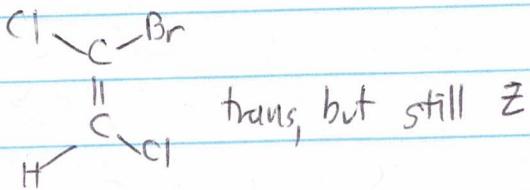

This nomenclature applies to other double bonds too:

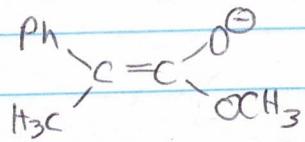

In cases of multiple bonds, numbers have to be assigned too:

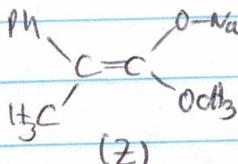

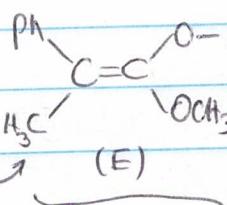

Z and E do not always correspond to cis and trans:

In the case of enolates, things can get confusing:

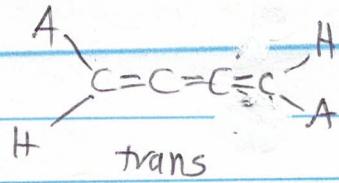

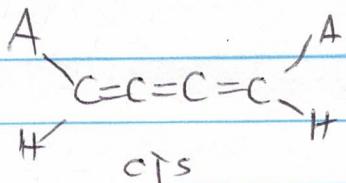

(E), if O-M bond is ionic, but \rightarrow

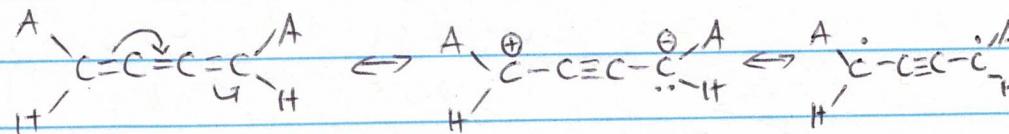

not recommended; instead, stick with the local cis/trans relationships

Cumulenes also have stereoisomers

they are more easily equilibrated

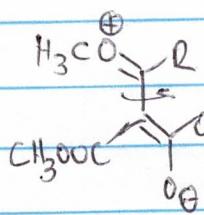

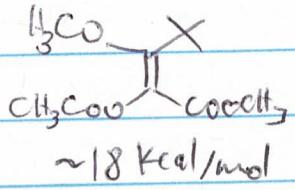

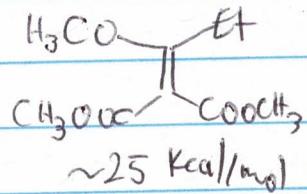

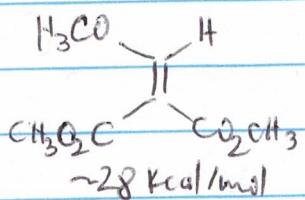

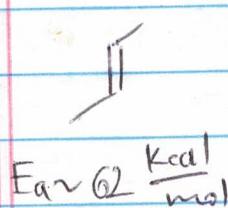

[3]cumulene barriers are 27-31 kcal/mol

[5] " " " even lower, ~19 kcal/mol

[7] and [9]cumulenes polymerize quickly and their barriers are unknown

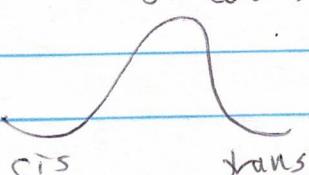

Some alkanes will also have low rotational barriers, and some are not going to be planar either. The two are often related:

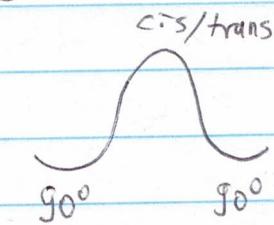

Free rotation is a consequence of both steric crowding and a favorable resonance structure

90° conformation

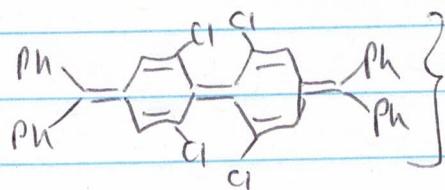

this is the common situation

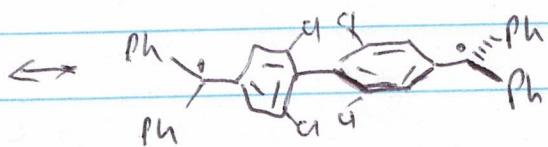

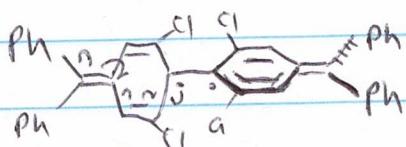

But in severely crowded alkenes, coplanarity becomes a transition state:

"negative" barrier to deplanarization

why in this specific molecule?

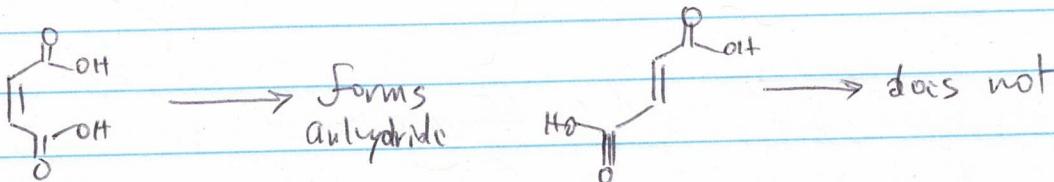

Aromaticity
+ steric crowding

is a hypothetical molecule, so far not prepared predicted to be twisted by 45° , with a rotation singlet barrier triplet split of $\sim 15 \text{ Kcal/mole}$

Methods to Distinguish Cis/trans Isomers

Chemical methods used to be very commonly employed, but are now largely outdated.

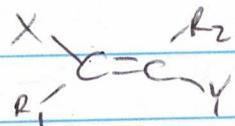

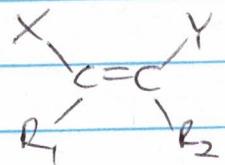

Physical methods are much more common and useful today.
Dipole moments differ:

Generally cis isomers are more polar, but that will depend based on whether the attached groups are similar or different in their electron-donating character.

This difference in dipole moments affects the IR and Raman spectra too. In IR, symmetrically substituted trans-alkenes are not visible, since μ remains zero; cis-substituted ones are. In the case of broken symmetry, cis-isomers still have higher intensity bands. NMR can tell a bit ~~by~~ about configuration by looking at chemical shifts, but in the case of non-equivalent protons, coupling constants are a lot more diagnostic:

$$X=Y=H, \quad {}^3J = +4 \text{ to } +12 \text{ Hz}$$

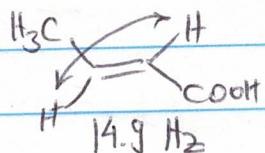

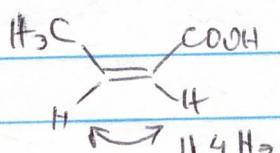

$$X=Y=F, \quad {}^3J = +15 \text{ to } +35 \text{ Hz}$$

$$\begin{array}{l} X=H \\ Y=F \end{array} \quad {}^3J = -4 \text{ to } +20 \text{ Hz}$$

$${}^3J = +12 \text{ to } +19 \text{ Hz}$$

$${}^3J = -115 \text{ to } -135 \text{ Hz}$$

$${}^3J = +10 \text{ to } +50 \text{ Hz}$$

In the cases where you don't have coupling nuclei, the following formula for chemical shifts can be used:

$$\delta_{C=CH} = 5.25 + Z_{gem} + Z_{trans} + Z_{cis}$$

↑ ↑
These generally differ for most substituents

TABLE 9.5. Parameters for Calculation of Proton Shift in the Alkene^a Shown in Figure 9.39

Substituent R	Z_i for R (ppm)		
	Z_{gem}	Z_{cis}	Z_{trans}
-H	0	0	0
-Alkyl	0.45	-0.22	-0.28
